This paper provides a tutorial introduction to a performance evaluation metric called the **isoefficiency function**. Traditional methods for evaluating serial algorithms are inadequate for analyzing the performance of parallel algorithm-architecture combinations. Isoefficiency function has proven useful for evaluating the performance of a wide variety of such combinations.

On a sequential computer, the fastest algorithm for solving a given problem is the best algorithm. However, the performance of a parallel algorithm for a specific problem instance on a given number of processors provides only limited information. The time taken by a parallel algorithm to solve a problem instance depends on the problem size, the number of processors used to solve the problem, and machine characteristics such as: processor speed, speed of communication channels, type of interconnection network, and routing techniques. An algorithm that yields good performance for a selected problem on a fixed number of processors on a given machine may perform poorly if any of these parameters are changed. Hence, the evaluation of a parallel algorithm on a parallel computer requires a more comprehensive analysis, and the study of scalability aids us in this analysis. The **scalability** of a parallel system is a measure of its capacity to deliver linearly increasing speedup with respect to the number of processors used. It reflects the capacity of the parallel system to effectively utilize an increasing amount of processing resources.

Scalability analysis of an architecture-algorithm combination helps us in answering the following questions: How does increasing the number of processors affect the performance of an algorithm? How does changing the problem size affect performance? How does changing the computation speed of the processors, or the communication speed of the interconnection network affect the performance of a parallel computer for a given algorithm? What is the best algorithm and architecture for solving a problem as the problem size and number of processors change?

A number of performance evaluation metrics have been developed to study the scalability of parallel algorithms and architectures [3, 4, 10, 11, 12]. Kumar and Gupta [7] provide a comprehensive survey of different methods of scalability analysis. The isoefficiency function is one such metric. It relates the size of the problem being solved to the number of processors required to maintain the efficiency at a fixed value. An important feature of the isoefficiency function is that it succinctly captures the effects of characteristics of the parallel algorithm as well as the parallel architecture on which it is implemented, in a single expression. The isoefficiency function enables us to determine the degree of scalability of a parallel system with respect to the number of processors, the speed of processors, and the communication bandwidth of the interconnection network. Thus

we can compare various combinations of parallel algorithms and architectures for a range of problem sizes and number of processors. Hence, using isoefficiency, we can determine the best parallel algorithm-architecture combination for a problem under a variety of situations without having to explicitly analyze all possible combinations under all possible conditions. The following sections present a discussion of the terminology necessary to use this metric followed by a number of useful examples of isoefficiency analysis.

1 Definitions and Assumptions

In this section, we introduce the terminology used in the rest of the paper. Since a parallel algorithm cannot be evaluated in isolation from the architecture it is implemented on, we define a parallel system as the combination of a parallel algorithm and a parallel architecture. Together, a parallel architecture and the parallel algorithm running on it constitute a **parallel system**. The time taken by an algorithm to execute on a single processor is called the **sequential execution time** and is denoted by T_1. The execution time of the corresponding parallel algorithm on p identical processors is called the **parallel execution time** and is denoted by T_P. A parallel algorithm incurs several overheads during execution. These include overheads due to idling, communication, and contention over shared data structures. The sum total of time spent by all processors doing work which is not done by the sequential algorithm is termed as the **total overhead** and is denoted by T_o. In general, T_o is a function of problem size and the number of processors. Since the sum total of time spent by all processors is pT_P, and the total overhead is T_o, we can see that

$$pT_P = T_1 + T_o$$

or

$$T_P = \frac{T_1 + T_o}{p} \tag{1}$$

The **speedup** (S) obtained from a parallel system is defined as the ratio of the sequential execution time to the parallel execution time. Therefore,

$$S = \frac{T_1}{T_P} = \frac{pT_1}{T_1 + T_o}$$

The **efficiency** (E) of a parallel system is defined as the ratio of the speedup obtained to the number of processors used. Therefore,

$$\begin{aligned} E &= \frac{S}{p} \\ &= \frac{T_1}{T_1 + T_o} \\ &= \frac{1}{1 + \frac{T_o}{T_1}} \end{aligned} \tag{2}$$

For certain parallel architecture-algorithm combinations, T_o can be negative. This implies that the speedup obtained from p processors may exceed p. This phenomenon is called superlinear speedup. An example of a parallel system capable of exhibiting such behavior is one in which

memory is hierarchical and the access time increases (in discrete steps) with the memory used by the program. In this case, the effective computation speed of a large program may be slower on a serial processor than on a parallel computer employing similar processors. This is because a sequential algorithm using M bytes of memory will use only M/p bytes on each processor of a p-processor parallel computer. In this case, cache and virtual memory effects may reduce the effective computation rate of a serial processor. In order to simplify presentation, we assume that T_o is non-negative in the rest of the paper.

During the course of analyzing parallel systems, we frequently encounter the notion of the size of the problem being solved. So far we have used this term informally without providing a rigorous definition. One way of expressing the **problem size** is to represent it by a parameter of the input size. For example, for any matrix problem involving $n \times n$ matrices the problem size could be denoted by n. A drawback of this definition is that the interpretation of problem size changes from one problem to another. For example, doubling the input size results in an 8-fold increase in the serial execution time for matrix multiplication and a 4-fold increase for matrix addition. A better definition of the size or the magnitude of the problem would be such that irrespective of the problem, doubling the problem size always means performing twice the amount of computation. Therefore, we choose to express problem size in terms of the total number of basic operations inherent in the problem. According to this notion, the problem size for $n \times n$ matrix multiplication is $\Theta(n^3)$, while that for the addition of two $n \times n$ matrices is $\Theta(n^2)$. In order to keep the problem size unique for a given problem, we define it as the number of operations the best sequential algorithm executes in order to solve the problem on a single processor. For some problems, the best algorithm is not known; for others, the asymptotically best algorithm may have worse performance than other algorithms for problem instances of interest. In these cases, we can use the number of operations in the serial algorithm that is considered best for such problem instances. For example, for matrix multiplication, the simple $\Theta(n^3)$ algorithm is often the algorithm of choice, even though Strassen's algorithm has a better asymptotic complexity. The problem size is a function of the size of the input. We will use the symbol W to denote problem size. If the cost of executing each operation is t_c, then $T_1 = Wt_c$.

We illustrate these terms using a simple example.

- **Example 1: Adding n numbers on a p-processor hypercube**

  Consider the problem of adding n numbers. For this problem the number of operations, and hence the problem size W is equal to n. If we assume that each addition takes t_c time, then T_1 is equal to nt_c. [1] Now consider a parallel algorithm for adding n numbers using a p-processor hypercube. This algorithm is shown in Figure 1 for $n = 16$ and $p = 4$. Each processors is allocated n/p numbers. In the first step of this algorithm, each processor locally adds its n/p numbers in $\Theta(n/p)$ time. The problem is now reduced to adding the p partial sums on p processors. These can be done by propagating and adding the partial sums as shown in Figure 1. A single step consists of one addition and one nearest neighbor communication of a single word, each of which is a constant time operation. For the sake of simplicity, let us assume that it takes one unit of time to add two numbers and also to communicate a number between two processors. Therefore, n/p time is spent in adding the n/p local numbers at each processor. After the local addition, the p partial sums are added in $\log p$ steps, each step consisting

[1] In reality the number of basic operations, W, is $n-1$ and the sequential execution time T_1 is given by $(n-1)t_c$. For large values of n, W and T_1 can be approximated by n and nt_c respectively.

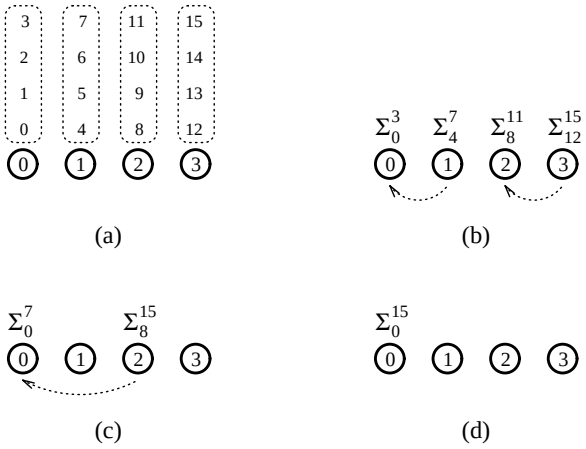

Figure 1: Computing the sum of 16 numbers on a 4-processor hypercube.

of one addition and one communication. Thus, the total parallel execution time T_p is $n/p + 2\log p$. The same task can be accomplished sequentially in n time units. Thus, out of the $n/p + 2\log p$ time units that each processor spends in parallel execution, n/p time is spent in performing useful work. The remaining $2\log p$ units of time per processor contribute to a total overhead of

$$T_o = 2p\log p \tag{3}$$

The speedup S and efficiency E for this algorithm are given by

$$S = \frac{T_1}{T_P} = \frac{n}{\frac{n}{p} + 2\log p} \tag{4}$$

$$E = \frac{S}{p} = \frac{n}{n + 2p\log p} \tag{5}$$

In the next section we formalize the notion of scalability of a parallel system.

2 Scalability of Parallel Systems

The number of processors used is an upper bound on the speedup achievable by a parallel system and the speedup for a single processor is one. If more than one processor is used, the speedup obtained is usually less than the number of processors. Let us further investigate how the speedup changes with the number of processors. Consider the problem of adding n numbers on a p-processor hypercube discussed in Example 1. Equations 4 and 5 can be used to calculate the speedup and efficiency for any given pair of n and p. Figure 2 plots speedup against number of processors for a few different values of n up to 32 processors. Table 1 shows the efficiencies corresponding to the values of n and p used in Figure 2.

Figure 2 and Table 1 illustrate two things. First, for a given problem instance, the speedup does not increase linearly as the number of processors is increased. The speedup curve tends to saturate. In other words, the efficiency drops with increasing number of processors. This phenomenon is true for all parallel systems, and is often referred to as Amdahl's law. Second, a larger instance of the same problem yields a higher speedup (efficiency) for the same number of processors.

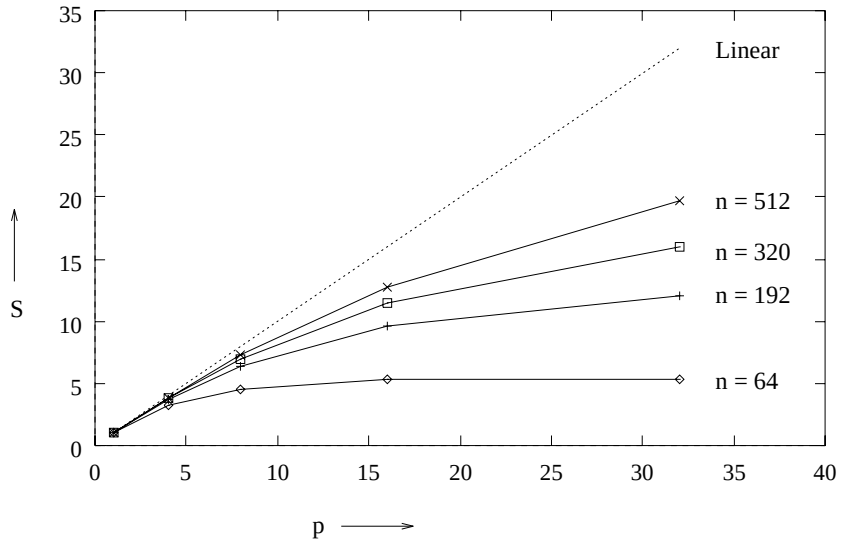

Figure 2: Speedup vs. number of processors for adding a list of numbers on a hypercube.

$p \rightarrow$ / $n \downarrow$	1	4	8	16	32
64	1.0	**.80**	.57	.33	.17
192	1.0	.92	**.80**	.60	.38
320	1.0	.95	.87	.71	.50
512	1.0	.97	.91	**.80**	.62

Table 1: Efficiency as a function of n and p for adding n numbers on p-p rocessor hypercubes.

Given that increasing the number of processors reduces efficiency and increasing the size of the computation increases efficiency, it should be possible to keep the efficiency constant by increasing both the size of the problem and the number of processors simultaneously. For instance, in Table 1, the efficiency of adding 64 numbers on a hypercube with four processors is 0.80. If the number of processors is increased to eight and the size of the problem is scaled up to add 192 numbers, the efficiency remains 0.80. Further increasing p to 16 and n to 512 also results in the same efficiency. This behavior is exhibited by a large class of parallel systems. For these systems, the efficiency of parallel execution can be maintained at a constant value by simultaneously increasing the number of processors and the size of the problem being solved. We call such systems **scalable** parallel systems.

2.1 The Isoefficiency Metric

We have defined a scalable parallel system as one in which efficiency can be kept constant as the number of processors is increased, provided that the problem size is also increased. A natural question is, "at what rate should the problem size be increased with respect to the number of

processors to keep the efficiency fixed?". For different parallel systems, the size of the problem to be solved has to increase at different rates in order to maintain a fixed efficiency as the number of processors is increased. This rate determines the degree of scalability of the parallel system. In this subsection we introduce a metric for quantitatively determining the degree of scalability of a parallel system.

Consider the efficiency of a parallel algorithm defined by Equation 2. Substituting $T_1 = t_c W$ into this equation, we get:

$$E = \frac{1}{1 + \frac{T_o}{t_c W}} \tag{6}$$

In Equation 6, if the problem size W is kept constant and p is increased, then the efficiency decreases because the total overhead T_o increases with p. If W is increased while keeping the number of processors constant, then, for scalable parallel systems, the efficiency increases. This is because for a given p, T_o grows slower than $\Theta(W)$. For these parallel systems, the efficiency can be maintained at a desired value (between 0 and 1) by increasing p, provided W is also increased. For different parallel systems, W has to be increased at different rates with respect to p in order to maintain a fixed efficiency. For example, in some cases, W might need to grow as an exponential function of p to keep the efficiency from dropping as p is increased. Such parallel systems are considered poorly scalable. On parallel systems with these characteristics, it is difficult to obtain good speedups for a large number of processors, unless the size of the problem being solved is enormously large. Conversely, if W needs to grow only linearly with respect to p, then the parallel system is considered highly scalable. This is because it delivers speedups increasing linearly with respect to the number of processors for problem sizes increasing at reasonable rates.

For scalable parallel systems, the efficiency can be maintained at a desired value (between 0 and 1) if the ratio T_o/W in the expression for efficiency is maintained at a constant value. To maintain a certain efficiency E ($0 < E < 1$), we manipulate Equation 6 to get:

$$\frac{T_o}{W} = t_c(\frac{1 - E}{E})$$

$$W = \frac{1}{t_c}(\frac{E}{1 - E})T_o$$

Let $K = E/(t_c(1 - E))$ be a constant depending on the efficiency. The equation above can be rewritten as follows:

$$W = KT_o \tag{7}$$

From Equation 7 the problem size W can usually be obtained as a function of p by algebraic manipulations. This function dictates the rate of growth of W required to keep the efficiency fixed as p is increased. We call this function the **isoefficiency function** of the parallel system. The isoefficiency function of a parallel system determines the ease with which it can achieve speedups increasing in proportion to the number of processors. A small isoefficiency function implies that small increments in the problem size are sufficient for efficient utilization of an increasing number of processing elements, and hence the parallel system is highly scalable. Conversely, a large isoefficiency function indicates a poorly scalable parallel system. The isoefficiency function does not exist for unscalable parallel systems because in such systems, the efficiency cannot be kept at constant value as p increases, no matter how fast the problem size is increased.

- **Example 2:**
  The expression for the overhead function of the problem of adding n numbers on a p-processor hypercube is given in Equation 3. Substituting the value of T_o in Equation 7, we get

$$W = 2Kp\log p \tag{8}$$

  Thus the asymptotic isoefficiency function for this parallel system is $\Theta(p\log p)$. This means that if the number of processors is increased from p to $p^{'}$, the problem size (in this case, n) will have to be increased by a factor of $p^{'}\log p^{'}/(p\log p)$ to get the same efficiency as on p processors. In other words, increasing the number of processors by a factor of $p^{'}/p$ requires n to be increased by a factor of $p^{'}\log p^{'}/(p\log p)$, in order to increase the speedup by a factor of $p^{'}/p$.

In the simple example of adding n numbers, the communication overhead is a function of only p. In general, it can depend on both the problem size and the number of processors. A typical overhead function may have several different terms of different orders of magnitude with respect to p and W. When there are multiple terms of different orders of magnitude in the overhead function, it may be impossible or cumbersome to obtain the isoefficiency function as a closed form function of p. For instance, consider a hypothetical parallel system, for which $T_o = p^{3/2} + p^{3/4}W^{3/4}$. In this case Equation 7 will be $W = Kp^{3/2} + Kp^{3/4}W^{3/4}$. It is difficult to solve for W in terms of p. Recall that the condition for constant efficiency is that the ratio of T_o and W should remain fixed. As p and W increase in a parallel system, the efficiency is guaranteed not to drop if none of the terms of T_o grow faster than W. Therefore, if T_o has multiple terms, we balance W against each individual term of T_o to compute the respective isoefficiency function. The component of T_o that causes the problem size to grow at the fastest rate with respect to p determines the overall asymptotic isoefficiency function of the computation.

- **Example: 3**

  Consider a hypothetical parallel algorithm-architecture combination for which $T_o = p^{3/2} + p^{3/4}W^{3/4}$. If we ignore the second term of T_o and use only the first term in Equation 7, we get

$$W = Kp^{3/2} \tag{9}$$

  Now consider only the second term of the overhead function and repeat the above analysis. Equation 7 now takes the form

$$W = Kp^{3/4}W^{3/4}$$

$$W^{1/4} = Kp^{3/4}$$

$$W = K^4p^3 \tag{10}$$

  In order to ensure that the efficiency does not decrease as the number of processors increase, the first and the second term of the overhead function require the problem size to grow as $\Theta(p^{3/2})$ and $\Theta(p^3)$, respectively. The asymptotically higher of the two rates should be regarded as the overall asymptotic isoefficiency function. Thus, the isoefficiency function is $\Theta(p^3)$ for this parallel system. This is because if the problem size W grows as $\Theta(p^3)$, then T_o would remain of the same order as W.

By performing isoefficiency analysis, we can test the performance of a parallel program on a few processors, and then predict its performance on a larger number of processors. However, the utility of the isoefficiency analysis is not limited to predicting the impact on performance of an increasing number of processors. As we shall see in later sections, it can also be used to study the behavior of a parallel system with respect to changes in other hardware related parameters, such as the speed of the processors and the data communication channels.

2.2 Cost-Optimality and Isoefficiency Function

A parallel system is **cost-optimal** if the product of the number of processors and the parallel execution time is proportional to the execution time of the best known serial algorithm on a single processor. In other words, a parallel system is cost-optimal if and only if

$$pT_P \propto W$$

Substituting T_P from the right hand side of Equation 1, we get

$$T_1 + T_o \propto W$$

Since $T_1 = Wt_c$, we have

$$Wt_c + T_o \propto W$$

$$W \propto T_o \tag{11}$$

Equation 11 suggests that a parallel system is cost-optimal if its overhead function and the problem size are of the same order of magnitude. This is exactly the condition required to maintain a fixed efficiency while increasing the number of processors in the parallel system (Equation 7). It follows then that conforming to the isoefficiency relation between the problem size and the number of processors is a way to retain the cost-optimality of a parallel system as it is scaled up.

2.3 A Lower Bound on Isoefficiency Function

We discussed earlier that a smaller isoefficiency function indicates better scalability. A natural question to ask then is: how small an isoefficiency function can be and what is an ideally scalable parallel system? If a problem consists of W basic operations, then no more than W processors can be used to solve the problem in a cost-optimal fashion. If the problem size grows at a rate slower than $\Theta(p)$ as the number of processors increases, then eventually the number of processors will exceed W, and, even in an ideal parallel system with no communication or other overheads, the efficiency will drop because the processors exceeding W will have no work to do. Thus asymptotically, the problem size has to increase at least as fast as $\Theta(p)$ to maintain a constant efficiency and hence $\Omega(p)$ is the asymptotic lower bound on the isoefficiency function. It also follows that the isoefficiency function of an ideally scalable parallel system is $\Theta(p)$.

2.4 Degree of Concurrency and Isoefficiency Function

The lower bound of $\Omega(p)$ is imposed on the isoefficiency function of a parallel system by the number of operations that can be performed concurrently. We define the maximum number of tasks that can

be executed simultaneously at any given time in a parallel algorithm as its **degree of concurrency**. The degree of concurrency is a measure of the number of operations that an algorithm can perform in parallel in a problem of size W and is independent of the parallel architecture. If $C(W)$ is the degree of concurrency of a parallel algorithm, then given a problem of size W, at most $C(W)$ processors can be employed effectively. For example, using Gaussian elimination to solve a system of n equations with n variables, the total amount of computation is $\Theta(n^3)$. However, the n variables have to be eliminated one after the other, and eliminating a particular variable involves $\Theta(n^2)$ computations. Thus, at most $O(n^2)$ processors can be kept busy at any given time. Now if $W = \Theta(n^3)$ for this problem, then the degree of concurrency $C(W)$ is $\Theta(W^{2/3})$. Since, if given a problem of size W, at most $\Theta(W^{2/3})$ processors can be used, then given p processors, the size of the problem should be at least $\Omega(p^{3/2})$ in order to use all the processors. Thus, the isoefficiency function of this computation due to concurrency is $\Theta(p^{3/2})$. The isoefficiency function due to concurrency is optimal (*i.e.*, $\Theta(p)$) only if the degree of concurrency of the parallel algorithm is $\Theta(W)$. If the degree of concurrency of an algorithm is less than $\Theta(W)$, then the isoefficiency function due to concurrency can be worse (greater) than $\Theta(p)$. In such cases, the overall isoefficiency function of a parallel system is given by the maximum of the isoefficiency functions due to concurrency, communication, and other overheads.

3 Illustrations of Isoefficiency Analysis

In this section, we illustrate the utility of isoefficiency analysis using different examples. Often we are faced with a need for comparing the performance of two parallel algorithms for a large number of processors. The asymptotic isoefficiency function provides us with such a tool. The algorithm with the smaller asymptotic isoefficiency function yields better performance as the number of processors becomes large. We illustrate this in Subsection 3.1 using the example of two parallel algorithms for computing the matrix-vector product. For certain parallel systems, changing speed of processors and communication channels impacts scalability moderately. However, for some other parallel systems, this impact is significant. This effect of machine specific parameters on the scalability is illustrated in Subsection 3.2 in the context of a parallel algorithm for computing Fast Fourier Transforms. Some parallel algorithms have low overhead due to communication, idling and contention, but offer limited concurrency. For many of these algorithms, concurrency plays a critical role in determining the overall isoefficiency. We illustrate this using Dijkstra's all pairs shortest path algorithm in Subsection 3.3. There are other algorithms which have a low overhead due to communication and idling, and offer a high degree of concurrency, but suffer from contention over shared data structures. For many of these algorithms, it is difficult to analytically model the overheads due to contention. In Subsection 3.4, we demonstrate in the context of the dynamic load balancing problem how the isoefficiency function can be used to determine the scalability of such algorithms.

3.1 Comparing two parallel algorithms

The asymptotic values of the isoefficiency function can be used to compare the performance of various algorithms as the number of processors becomes large. We illustrate this using the example of two parallel algorithms for computing a matrix-vector product on a hypercube connected

computer.

- **Example 4: Stripe Based Matrix-Vector Product on a Hypercube**

  Consider the problem of multiplying an $n \times n$ matrix with an $n \times 1$ vector. The number of basic operations needed for this matrix-vector product, and the problem size W is equal to n^2. If the time taken by a single addition and multiplication operation is t_c, then the sequential execution time of this algorithm is $n^2 t_c$; *i.e.*, $T_1 = n^2 t_c$ [5].

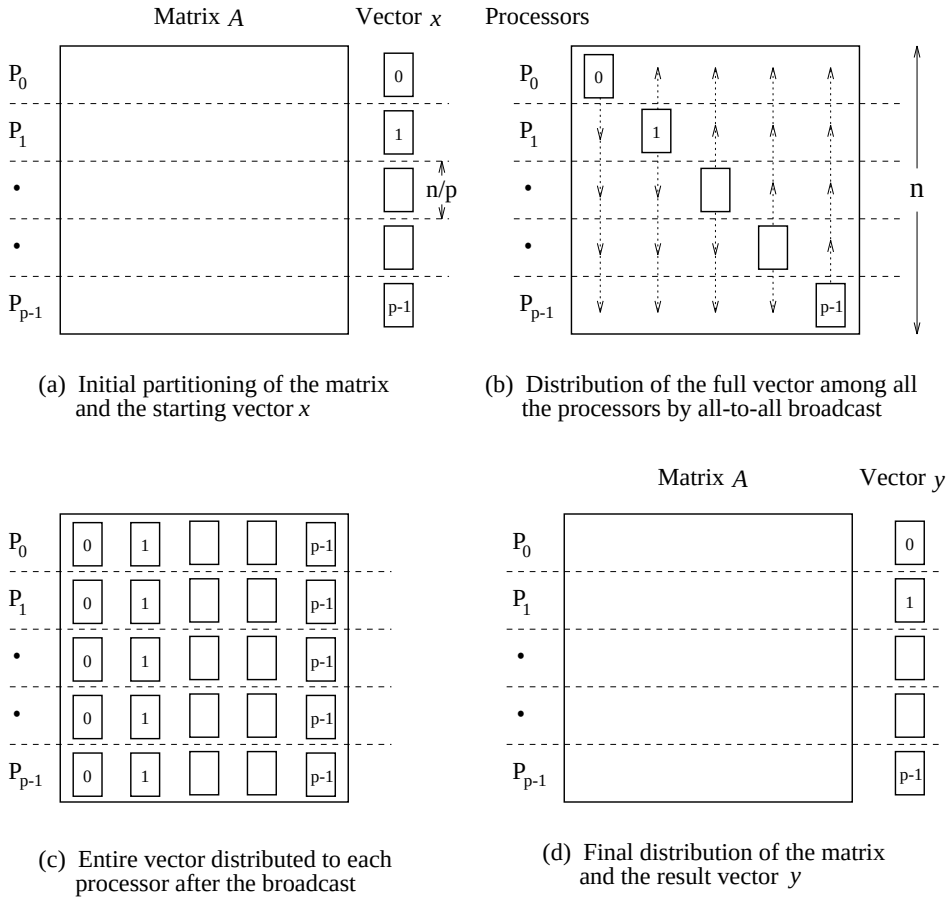

Figure 3: Multiplication of an $n \times n$ matrix with an $n \times 1$ vector using row-wise striped data partitioning.

Figure 3 illustrates a parallel formulation of this algorithm based on striped partitioning of the matrix and the vector. Each processor is assigned n/p rows of the matrix and n/p elements of the vector. Since the matrix-vector multiplication requires the vector to be multiplied with each row of the matrix, every processor needs the entire vector. In order to accomplish this, in the first step, each processor broadcasts its n/p elements of the vector to every other processor. This operation is also referred to as an all-to-all broadcast. After this step, each processor has the vector available locally and n/p rows of the matrix. Using these, it computes the dot products locally, and at the end of this step, each processor has n/p elements of the resulting vector.

Let us now analyze the performance of this parallel formulation for a hypercube connected computer. The first step of the algorithm involving the all-to-all broadcast of packets of size n/p among p

processors can be performed in $t_s \log p + t_w n(p-1)/p$ time [5]. Here, t_s is the startup time of the communication network and t_w is the per-word transfer time. For large values of p this can be approximated to $t_s \log p + t_w n$. Assuming that an addition and a multiplication takes t_c units of time, each processor spends $t_c n^2/p$ units of time in multiplying its n/p rows with the vector. Thus, the parallel execution time of this procedure is given by:

$$T_P = t_c \frac{n^2}{p} + t_s \log p + t_w n \tag{12}$$

The corresponding speedup S and efficiency E are given by:

$$S = \frac{p}{1 + \frac{p(t_s \log p + t_w n)}{t_c n^2}} \tag{13}$$

$$E = \frac{1}{1 + \frac{t_s p \log p + t_w np}{t_c n^2}} \tag{14}$$

Now we derive an expression for the isoefficiency function for this parallel formulation. Using the relation $T_o = pT_P - T_1$, we get the following expression for the overhead function of the striped matrix-vector multiplication on the hypercube:

$$T_o = t_s p \log p + t_w np \tag{15}$$

We can determine the isoefficiency function from the equation $W = KT_o$ (Equation 7). Let us rewrite this relation for our parallel formulation of matrix-vector multiplication, first with only the t_s term of T_o.

$$W = Kt_s p \log p \tag{16}$$

Equation 16 gives the isoefficiency term with respect to the message startup time. Similarly, the t_w term of the overhead function can be balanced against the problem size W as follows:

$$n^2 = Kt_w np$$

$$n = Kt_w p$$

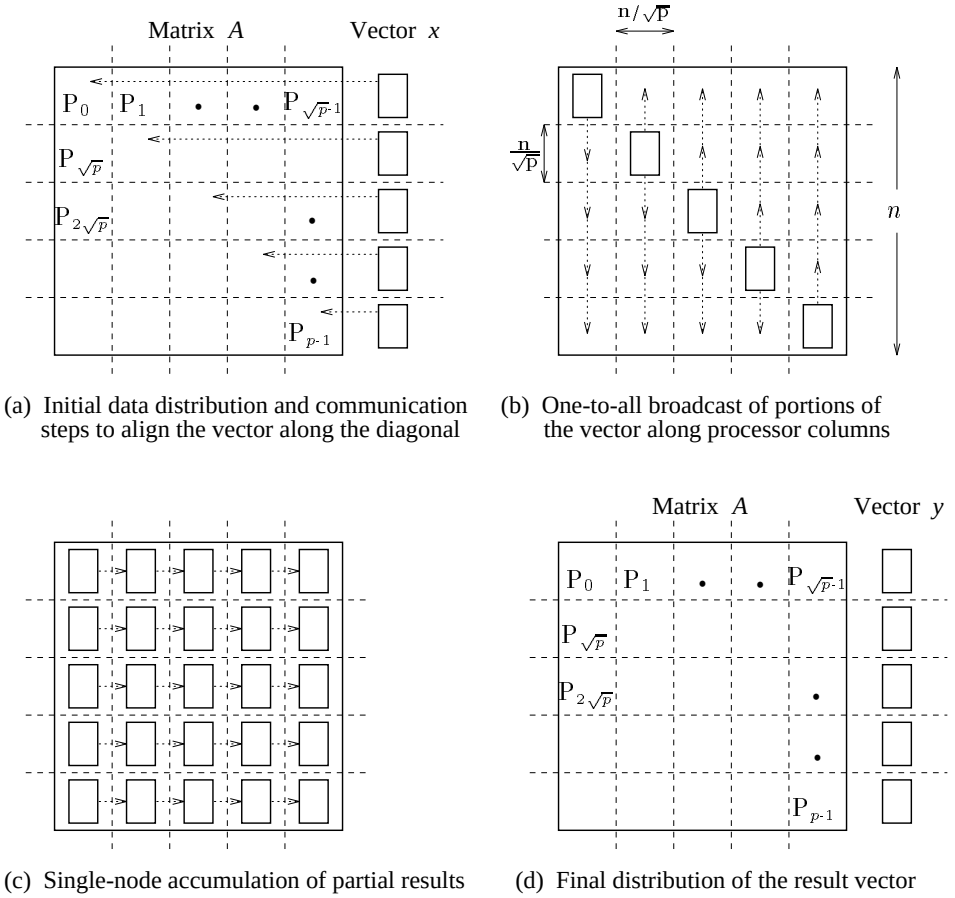
$$W = n^2 = K^2 t_w^2 p^2 \tag{17}$$

From Equations 16 and 17 it can be inferred that the overall asymptotic rate at which the problem size needs to increase with the number of processors in order to maintain a fixed efficiency is $\Theta(p^2)$.

- **Example 5: Checkerboard Based Matrix-Vector Product on a Hypercube**

Consider an alternate partitioning of the matrix and the vector for computing the matrix-vector product. Instead of partitioning the matrix into stripes, we now divide it into p squares, each of dimensions $(n/\sqrt{p}) \times (n/\sqrt{p})$. This partitioning is referred to as checkerboard partitioning [5]. The parallel matrix-vector multiplication algorithm based on this partitioning is illustrated in Figure 4. The vector itself is distributed along the last column of the mesh.

In the first step of the algorithm, the vector is aligned along the diagonal processors. For this, all processors of the last column send their $n/\sqrt{p}$ elements of the vector to the diagonal processor of their respective rows. Then a column-wise one-to-all broadcast of these $n/\sqrt{p}$ elements is performed.



(a) Initial data distribution and communication steps to align the vector along the diagonal

(b) One-to-all broadcast of portions of the vector along processor columns

(c) Single-node accumulation of partial results

(d) Final distribution of the result vector

Figure 4: Matrix-vector multiplication using checkerboard partitioning.

After this communication step, the vector is aligned along the rows of the matrix. Each processor performs n^2/p multiplications and locally adds up the $n/\sqrt{p}$ sets of products. As shown in Figure 4(c), each processor now has $n/\sqrt{p}$ partial sums which need to be accumulated along each row to obtain the resultant vector. Hence, the last step of the algorithm is a single node accumulation of these $n/\sqrt{p}$ values in each row, with the last processor of the row as the destination. The operation of this algorithm is illustrated in Figure 4.

We now analyze the performance of this algorithm on a hypercube connected computer with store and forward routing [5]. The first step of sending a message from the last processor of a row to the diagonal processor can be performed in at most $t_s + t_w(n/\sqrt{p})\log\sqrt{p}$. The second communication step distributes copies of the vector among the rows of processors and involves one-to-all broadcasts in all the columns of processors as shown in Figures 4(b) and 4(c). This step can be performed in $(t_s + t_w n/\sqrt{p})\log\sqrt{p}$. If a multiplication and an addition is assumed to take t_c units of time, then each processors spends approximately $t_c n^2/p$ time performing computation. Now if the resultant vector has to be placed in the last column of processors like the starting vector, then a single node accumulation of components of size $n/\sqrt{p}$ of the vector has to be performed in each row of processors. Ignoring the time required for performing additions during this step, the accumulation can be performed with a communication time of $(t_s + t_w n/\sqrt{p})\log\sqrt{p}$. Summing up the time taken by all the steps, the total parallel execution time for this procedure is given by the following equation :

$$T_P = t_c \frac{n^2}{p} + t_s + 2t_s \log\sqrt{p} + 3t_w \frac{n}{\sqrt{p}} \log\sqrt{p}$$

This can be approximated by

$$T_P = t_c \frac{n^2}{p} + t_s \log p + \frac{3}{2} t_w \frac{n}{\sqrt{p}} \log p \tag{18}$$

From this equation, the total overhead T_o is given by:

$$T_o = t_s p \log p + \frac{3}{2} t_w n \sqrt{p} \log p$$

As before, we can equate each term in this overhead function with the problem size W. For the isoefficiency due to t_s, we have $W \propto K t_s p \log p$, where $K = 1/(t_c(1-E))$. For isoefficiency due to t_w, equating W with KT_o, we have

$$n^2 t_c = K \frac{3}{2} t_w n \sqrt{p} \log p$$

$$n = K \frac{3}{2} \frac{t_w}{t_c} \sqrt{p} \log p$$

$$n^2 = K^2 \frac{9}{4} \frac{t_w^2}{t_c^2} p \log^2 p$$

Therefore, the isoefficiency due to t_w is given by $\Theta(p \log^2 p)$. Since this term asymptotically dominates the $\Theta(p \log p)$ term due to t_s, the overall isoefficiency of this formulation is given by $\Theta(p \log^2 p)$.

From these two examples, we can see that the isoefficiency function of the stripe based matrix-vector product algorithm is $\Theta(p^2)$, because it is asymptotically higher than the $\Theta(p \log^2 p)$ isoefficiency function of the checkerboard based algorithm. This implies that as the number of processors is increased, the stripe based formulation will require much larger problem sizes to yield the same efficiencies as the checkerboard based formulation.

3.2 Predicting effects of machine specific parameters

Isoefficiency analysis can be used to predict the effect of such machine specific parameters as processor speed and speed of communication channels (startup time, per-word transfer time, *etc.*). In this section, we illustrate how isoefficiency analysis is useful in making such predictions.

- **Example 6: Fast Fourier Transforms**

  Consider the Cooley-Tukey algorithm for computing an n-point single dimensional unordered radix-2 FFT [2, 5]. Figure 5 illustrates the algorithm graphically. The sequential complexity of this formulation is given by $\Theta(n \log n)$. In this section, we will use a parallel formulation of this algorithm based on the **binary exchange method** for a hypercube based computer. In this parallel formulation, shown in Figure 5, we partition the vectors into blocks of n/p contiguous elements and assign one such block to each processor. Let the hypercube being used be d-dimensional (*i.e.*, $p = 2^d$) and let $n = 2^r$. An interesting property of the mapping shown in Figure 5 is that the vector elements residing on different processors are combined during the first d iterations, while the pairs of elements combined during the

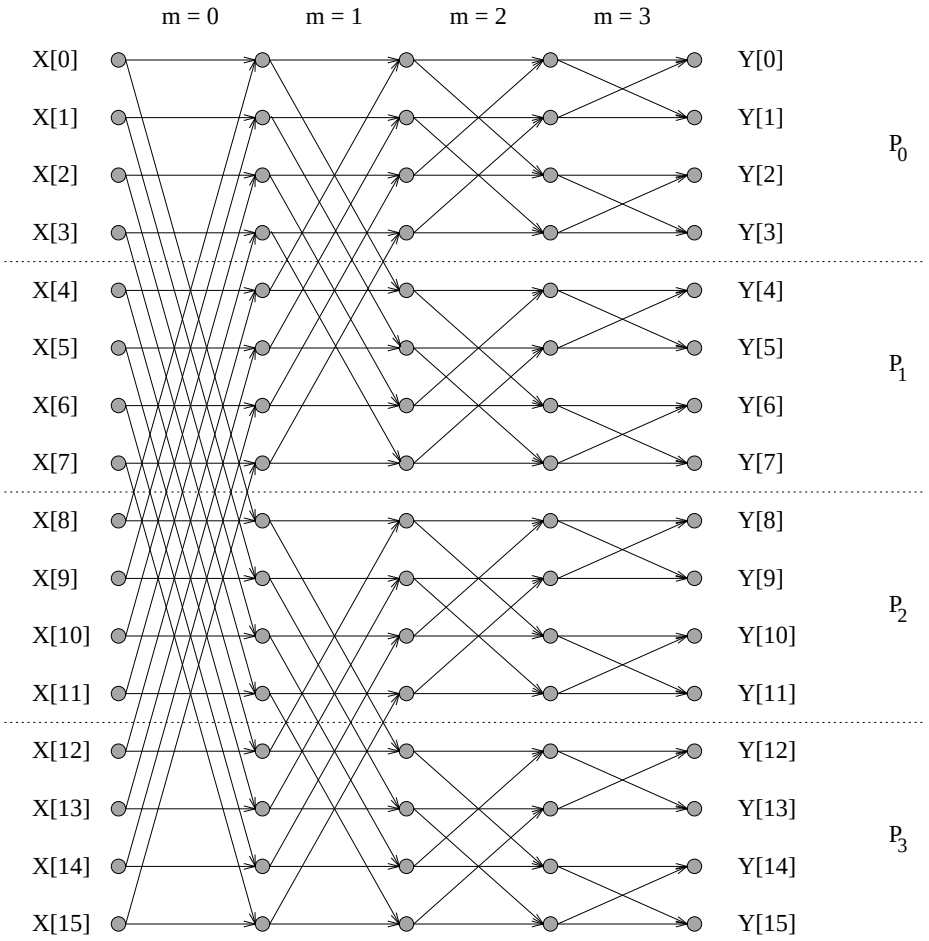


Figure 5: A 16-point FFT on four processors. P_i denotes processor number i and m refers to the iteration number.

last $(r-d)$ iterations reside on the same processors. Hence, this parallel FFT algorithm involves interprocessor communication only during $d = \log p$ of the $\log n$ iterations. Each communication operation involves exchanging n/p words of data. Thus, the time spent in communication during the execution of the entire algorithm is $(t_s + t_w n/p) \log p$. In each iteration, a processor updates n/p elements of vector R. If a complex multiplication and addition takes time t_c, then the parallel execution time of the n-point parallel FFT on a p-processor hypercube is given by:

$$T_P = t_c \frac{n}{p} \log n + t_s \log p + t_w \frac{n}{p} \log p \tag{19}$$

From this equation, we can also see that the total overhead T_o is given by:

$$T_o = t_s p \log p + t_w n \log p$$

We know that the problem size for an n-point FFT is given by:

$$W = n \log n \tag{20}$$

Following the methodology of Examples 4 and 5, we can determine the isoefficiency by equating the problem size with the total overhead. For isoefficiency due to t_s, we have $W \propto t_s p \log p$, which

corresponds to an isoefficiency function of $\Theta(p \log p)$. The isoefficiency due to the t_w term can also be determined similarly:

$$\begin{aligned} n \log n &= K t_w n \log p \\ \log n &= K t_w \log p \\ n &= p^{K \frac{t_w}{t_c}} \\ n \log n &= K t_w p^{K t_w} \log p \end{aligned}$$

$$W = \frac{E}{1-E} \frac{t_w}{t_c} p^{\frac{E}{1-E} \frac{t_w}{t_c}} \log p \tag{21}$$

If the term $t_w E/(t_c(1-E))$ is less that 1, then the rate of growth of problem size dictated by Equation 21 is less than $\Theta(p \log p)$, and hence the overall isoefficiency function is $\Theta(p \log p)$ for this parallel system. On the other hand, if $t_w E/(t_c(1-E))$ exceeds 1, then Equation 21 determines the overall isoefficiency function which is now greater than $\Theta(p \log p)$. Also, in this case, the asymptotic isoefficiency function depends on the relative values of $E/(1-E)$, t_w and t_c. Thus, the FFT algorithm is somewhat unique in that the asymptotic isoefficiency function is a function of the desired efficiency and hardware dependent parameters. In fact the efficiency corresponding to $t_w E/(t_c(1-E)) = 1$, (*i.e.*, $E/(1-E) = t_c/t_w$, or $E = t_c/(t_c + t_w)$) acts as a threshold value. For a given hypercube connected computer with fixed t_c and t_w, efficiencies up to this values can be obtained easily. But efficiencies much higher than this threshold can be obtained only if the problem size is extremely large.

Let us examine the effect of the value of $t_w E/(t_c(1-E))$ on the isoefficiency function. Consider the computation of an n-point FFT on a p-processor hypercube on which $t_w = t_c$. The isoefficiency function of the parallel FFT on this machine is $E/(1-E)p^{E/(1-E)} \log p$. Now for $E/(1-E) \leq 1$ (*i.e.* $E \leq 0.5$) the overall isoefficiency is $\Theta(p \log p)$, but for $E > 0.5$, the isoefficiency function is much worse. For instance, if $E = 0.9$, then $E/(1-E) = 9$ and hence the isoefficiency function becomes $\Theta(p^9 \log p)$. Now consider the computation of an n-point FFT on a p-processor hypercube on which $t_w = 2t_c$. The threshold efficiency is 0.33. The isoefficiency function for $E = 0.33$ is $\Theta(p \log p)$, for $E = 0.5$ it is $\Theta(p^2 \log p)$, and for $E = 0.9$ it becomes $\Theta(p^{18} \log p)$.

The above examples show that there is a limit on the efficiency that can be obtained for reasonable problem sizes, and this limit is determined by the ratio of the CPU speed and the bandwidth of the communication channels of the hypercube. This limit can be raised by increasing the bandwidth of the communication channels. On the other hand, making the CPU's faster without improving the communication bandwidth lowers this threshold. Hence, this parallel formulation of FFT performs poorly on a hypercube whose communication and computation speeds are not balanced. If the hardware is balanced with respect to communication and computation speeds, then the FFT algorithm is fairly scalable on a hypercube with an overall isoefficiency function of $\Theta(p \log p)$, and good efficiencies can be expected for reasonably large number of processors.

This example illustrates how the isoefficiency function can be used to derive the effect of various machine specific factors. For a more detailed scalability analysis of this and other parallel FFT algorithms, see [2, 5].

3.3 Impact of Concurrency on Scalability

We have seen that the maximum concurrency in a parallel algorithm often limits the number of processors that can be effectively utilized. Therefore, the problem size has to grow fast enough

so that it is possible to use the increased number of processors. For many algorithms limitations imposed by concurrency plays a dominant role in determining overall scalability. We illustrate this in the context of Dijkstra's all pairs shortest path algorithm.

- **Example 7: Dijkstra's All Pair's Shortest Path Algorithm**

  Consider the all-pairs shortest path problem for a dense graph with n vertices. The problem involves finding the shortest path between each pair of vertices in the graph. The best known serial algorithm for solving this takes time $\Theta(n^3)$ time. This problem can also be solved using n instances of the single-source shortest path problem. The single source shortest path problem determines the shortest path from one vertex to every other vertex in the graph. The sequential complexity of the single-source shortest path problem is $\Theta(n^2)$. Therefore, by executing one instance of the single-source shortest path algorithm for each of the n vertices, we can solve the all-pairs shortest path problem.

  A simple parallel formulation of this algorithm can be derived by using n processors with each processor executing a single-source shortest path problem independently. Since each of these computations is independent of the other, the parallel formulation requires absolutely no communication. It may therefore seem that this algorithm is the best possible algorithm.

  Let us consider the scalability resulting from the concurrency in this parallel algorithm. Since the algorithm can use at most n processors, $p = n$, and since the problem size W is $\Theta(n^3)$, W must grow at least as $\Theta(p^3)$ to be able to use additional processors. This function determines the overall isoefficiency of the parallel formulations. This isoefficiency is relatively high and other algorithms with better isoefficiencies are available.

This example illustrates how isoefficiency captures the concurrency inherent in a parallel algorithm. An algorithm may appear attractive because of lack or absence of communication, but may indeed perform poorly for higher number of processors because of limited concurrency. See [5, 9] for scalability analysis of a number of other shortest-path algorithms.

3.4 Impact of Contention for Shared Data Structures

For some parallel algorithms, it is difficult to compute the parallel execution time analytically, as the effects of certain overheads such as those due to contention are difficult to model. In such applications, isoefficiency analysis may still be a useful tool for analyzing the scalability. In this subsection, we present one such parallel algorithm.

- **Example 8: Dynamic Load Balancing**

  Consider an application with the following characteristics:

  - The work available at any processor can be partitioned into independent work pieces as long as it is more than some non-decomposable unit.
  - It is difficult to estimate the amount of computation associated with a piece of work.
  - A reasonable work splitting mechanism is available; *i.e.*, if work w at one processor is partitioned into two parts ψw and $(1-\psi)w$, then there exists an arbitrarily small constant $\alpha(>0)$, such that $\psi w > \alpha w$ and $(1-\psi)w > \alpha w$. The role of α is to set a bound on the load imbalance resulting from work splitting.

Instances of applications which conform to these characteristics are found in depth first search of large unstructured trees used for solving discrete optimization problems [6]. Some parallel algorithms for solving this problem employ the following dynamic load balancing strategy. All work is initially assigned to one processor. An idle processor P_i selects a processor P_a using some selection criterion and sends it a work request. If processor P_a has no work, then it responds with a reject message; else, it partitions its work into two parts and sends one of the pieces to P_i. This process continues until all processors exhaust the available work. Various selection criteria have been proposed in literature [6, 8]. One technique referred to as Global Round Robin (GRR) maintains a global pointer G located at one of the processors. This pointer initially points to the first processor in the ensemble. Each time an idle processor needs to select P_a, it reads the current value of G, and requests work from P_G. Before the next request from an idle processor is processed, the global pointer is incremented by one (modulo p). The global pointer distributes the work requests evenly over the various processors.

We can see that the non-deterministic nature of the algorithm makes it impossible to evaluate the exact parallel execution time of such an algorithm. However, it is possible to bound the communication cost of such an algorithm. As shown in [6, 5], an upper bound on the number of communications required for this algorithm is $O(p \log W)$. Each communication takes $O(\log p)$ time, and the total overhead resulting from the communication of work is bounded by $O(p \log p \log W)$. As before, this term can be equated with the problem size W to yield the isoefficiency resulting from communication overheads. Therefore,

$$W \propto O(p \log p \log W)$$

Substituting the value of W from the right hand side of the expression back into the right hand side and ignoring the double log terms, we can see that the isoefficiency of this algorithm due to communication overheads is $O(p \log^2 p)$.

This term however does not specify the overall isoefficiency of the system because the algorithm has overheads in addition to that for communicating work. In this algorithm a global variable is accessed repeatedly. If many processors try to access it at the same time, then only one will succeed, and others will have to wait due to contention. We analyze the isoefficiency due to contention as follows:

The global variable is accessed $O(p \log W)$ number of times (for read and increment operations) over the entire execution. If processors are efficiently utilized, then the total time of execution is $\Theta(W/p)$. Assume that while solving some specific problem instance of size W on p processors, there is no contention. In this case, W/p is much more than the total time over which the shared variable is accessed. Now, as we increase the number of processors, the total time of execution (*i.e.*, W/p) decreases but the number of times the shared variable is accessed increases. There is thus a crossover point beyond which the shared variable access will become a bottleneck and the overall execution time cannot be reduced further. This bottleneck can be eliminated by increasing W at a rate such that the ratio between W/p and $O(p \log W)$ remains the same. Equating W/p and $O(p \log W)$ and simplifying yields an isoefficiency term of $O(p^2 \log p)$.

Thus, since the isoefficiency due to contention asymptotically dominates the isoefficiency due to communication, the overall isoefficiency is given by $O(p^2 \log p)$.

In this example, we have seen how it is possible to model overheads due to contention using the isoefficiency metric. A number of other dynamic load balancing algorithms have been analyzed in [6, 8]. In [6], it is experimentally shown that dynamic load balancing schemes with better isoefficiency functions outperform those with poorer isoefficiency functions.

4 Summary and Concluding Remarks

The isoefficiency metric is useful in situations in which we are interested in obtaining linearly increasing performance with the number of processors. If the rate of growth of problem size is the same as that specified by the isoefficiency function, then the speedup obtained from the parallel system is linear. In certain cases, it may not be possible or desirable to increase the problem size at the rate specified by the isoefficiency function. If this rate is smaller than the isoefficiency then the speedup is sublinear. For a given rate of growth of problem size, the speedup curve can be used as a scalability metric. If the problem size is increased linearly with the number of processors, the speedup curve is referred to as scaled speedup [3]. The rate of growth of problem size may also be constrained by the amount of memory in the parallel computer. In this case, the problem size is increased at the fastest rate allowed by the available memory. These metrics have been investigated by Worley [12], Gustafson [3] and Sun and Ni [10]. In many situations, the rate of growth of problem size is dictated by the time available to solve the problem. In these cases, the problem size is increased with number of processors in such a way that the parallel runtime remains constant. The scalability issues for such problems have been explored by Worley [12], Gustafson [3], and Sun and Ni [10]. It is also possible to keep the problem size fixed and use the speedup curve as a scalability metric. Performance issues related to fixed problem size case have been addressed in [1].

There are certain interesting relationships between isoefficiency and some of these metrics. It can be shown that if the isoefficiency function is greater than $\Theta(p)$, then for a scalable parallel system, the problem size cannot be increased indefinitely while maintaining a fixed execution time, no matter how many processors are used [1, 7]. In [1], we have shown that for a class of parallel systems, the relationship between the problem size and the number of processors on which the problem executes in minimum time is specified by the isoefficiency function.
